# **Abstract**

Despite the recent advancements of vision-language-action (VLA) models on a variety of robotics tasks, they suffer from critical issues such as poor generalizability to unseen tasks, due to their reliance on behavior cloning exclusively from successful rollouts. Furthermore, they are typically fine-tuned to replicate demonstrations collected by experts under different settings, thus introducing distribution bias and limiting their adaptability to diverse manipulation objectives, such as efficiency, safety, and task completion. To bridge this gap, we introduce **GRAPE**: Generalizing Robot Policy via Preference Alignment. Specifically, GRAPE aligns VLAs on a trajectory level and implicitly models reward from both successful and failure trials to boost generalizability to diverse tasks. Moreover, GRAPE breaks down complex manipulation tasks to independent stages and automatically guides preference modeling through customized spatiotemporal constraints with keypoints proposed by a large vision-language model. Notably, these constraints are flexible and can be customized to align the model with varying objectives, such as safety, efficiency, or task success. We evaluate GRAPE across a diverse array of tasks in both real-world and simulated environments. Experimental results demonstrate that GRAPE enhances the performance of state-of-the-art VLA models, increasing success rates on in-domain and unseen manipulation tasks by 51.79% and 60.36%, respectively. Additionally, GRAPE can be aligned with various objectives, such as safety and efficiency, reducing collision rates by 44.31% and rollout step-length by 11.15%, respectively. All code, models, and data are available at https://grape-vla.github.io/.

# 1. Introduction

The recent rapid proliferation of vision-language-action (VLA) models has streamlined general robotic manipulation tasks, demonstrating impressive capability across a

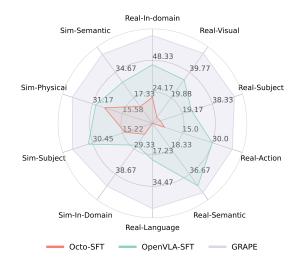

Figure 1. Comparison of GRAPE with SOTA VLA models finetuned on the same data across a large variety of generalization and in-domain tasks in both real-world and simulated environments.

range of tasks under controlled environmental variations [4, 7, 26, 44]. However, these models face several critical challenges such as poor generalizability across new environments, objects, tasks, and semantic contexts [26]. A significant factor contributing to this limitation is their reliance on *supervised fine-tuning* (SFT), where VLAs simply imitate actions from successful rollouts via behavior cloning while not developing a holistic understanding of the task goal or potential failure patterns [27]. While reinforcement learning (RL) algorithms such as PPO [42] have proved promising in enhancing their generalizability [52], the high cost of gathering sufficient online trajectories and explicitly defining reward make them impractical for training VLA [44].

Furthermore, training VLAs to solely replicate expert behaviors often results in *behavior collapse* [28] where the planned trajectories are often suboptimal [26]. This is because the SFT datasets are usually uncurated and consist of offline demonstrations collected from experts that embed implicitly different values (e.g. task completion, safety, and cost-efficiency) that are not clearly defined within the data [36, 45]. Simply imitating these behaviors via SFT can potentially confuse the model and result in subopti-

<sup>\*</sup>Equal Contribution. Correspondence to Huaxiu Yao at <huaxiu@cs.unc.edu>

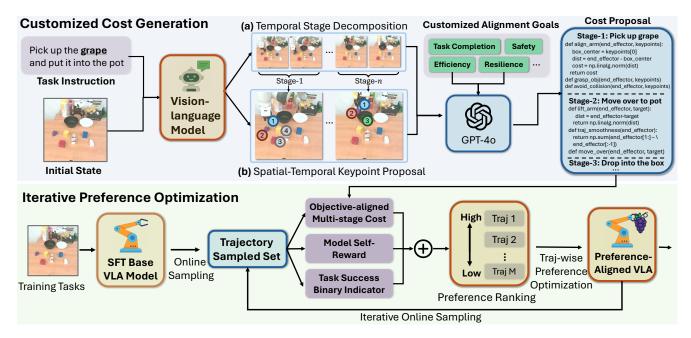

Figure 2. **Overview of GRAPE.** Given a complex manipulation task (**top**), GRAPE first adopts a vision-language model to decompose the task into several temporal stages, then identifies spatial keypoints essential for each stage's subtask completion. Then given user-specified alignment goals, GRAPE prompts a powerful vision-language model to obtain a series of cost functions for each stage, where lower cost implies higher alignment compliance. During iterative preference optimization (**bottom**), we sample multiple offline trajectories from the base VLA model and obtain trajectories with associated multi-stage costs. This score further incorporates the model's self-evaluation of each trajectory and a binary task success indicator. Then we rank the sampled trajectories with their corresponding scores to obtain a list of preferences. Then we perform a trajectory-wise preference optimization to obtain a improved model, from which we further sample online trajectories and iterate until convergence.

mal trajectories that deviate from the actual objective of the demonstrations. Some approaches attempt to address this challenge by explicitly defining a set of objectives and solving them hierarchically [24]. However, this approach incurs additional inference overhead and lacks scalability [30].

To address these issues, we propose **GRAPE**: Generalizing Robot Policy via Preference Alignment to alleviate the high cost of training VLAs with RL objective, while offering flexibility for aligning towards customized manipulation objectives. As shown in Figure 2, GRAPE introduces trajectory-wise preference optimization (TPO) to align VLA policies on a trajectory level by implicitly modeling reward from both successful and failure trials, boosting generalizability to diverse tasks. To further alleviate the difficulty in ranking trajectories and providing preferences towards arbitrary alignment objectives, GRAPE proposes to decompose the complex manipulation tasks into multiple independent stages and adopt a large vision model to propose keypoints for each stage, each associated with a spatial-temporal constraint. Notably, these constraints are flexible and can be customized to align the model with varying manipulation objectives, such as task completion, robotinteraction safety, and cost-efficiency. We evaluate GRAPE across a wide range of real-world tasks and two simulated environments. Experimental results show that GRAPE outperforms state-of-the-art VLA models, improving success rates on both in-domain and unseen manipulation tasks by 51.79% and 60.36%, respectively. Moreover, GRAPE can be aligned to diverse objectives such as safety and efficiency, to further reduce collision rate by 44.31% and roll-out step-length by 11.15%, respectively.

# 2. Generalizing Robot Policy via Preference Alignment

## 2.1. Preliminaries

During inference, a VLA typically initializes with an task instruction q, and at each timestep t, it takes an environment observation  $o_t$  (usually an image) and outputs an action  $a_t$ , where we can denote  $\pi_{\theta}(a_i|(o_i,q))$  as the action policy of a VLA parameterized by  $\theta$ . To complete the task, VLA iteratively interacts with the environment and obtains a trajectory  $\zeta = \{o_1, a_1, \cdots, o_T, a_T|q\}$  of length T. Typically, VLAs are fine-tuned to imitate expert behaviors via SFT:

$$\mathcal{L}_{SFT} = -\sum_{(\zeta,q)\in\mathcal{D}} \sum_{t=1}^{T} \log p(a_t|o_t, q; \pi_{\theta}), \tag{1}$$

where  $\mathcal{D} = \{(\zeta_1, q_1), \dots, (\zeta_N, q_N)\}$  denotes the training set containing N expert trajectories. Specifically,  $\mathcal{L}_{SFT}$  en-

forces VLA to memorize the action associated with each observation sampled from a distribution  $\mathbb{P}_{\mathcal{D}}$ , resulting in poor generalizability to new task settings. It is worth to note that while we follow Brohan et al. [7], O'Neill et al. [36] and consider the step-wise policy based on the Markov decision process (MDP) assumption [43], our approach can be easily adapted to both non-MDP case which takes past interaction histories (usually a video or a series of images) as state [9] and diffusion policy [16] which generates multiple future steps all at once [44].

# 2.2. TPO: Trajectory-wise Preference Optimization

To improve generalization, we follow Bai et al. [3], Schulman et al. [42] and further fine-tune VLA policies via RL objective. Let  $r_{\phi}$  denote a reward function parameterized by  $\phi$ , we have

$$\max_{\pi_{\theta}} \mathbb{E}_{\zeta \sim \pi_{\theta}} \left[ r_{\phi}(\zeta) \right] - \beta D_{\text{KL}} \left[ \pi_{\theta}(\zeta) \parallel \pi_{\text{ref}}(\zeta) \right], \quad (2)$$

where  $\beta$  controls the deviation from the base reference policy  $\pi_{\rm ref}$  trained via SFT in Eq. (1) and  $\pi(\zeta,q)$  is the likelihood of policy  $\pi$  generating the entire trajectory  $\zeta$  under instruction q. Then we follow Rafailov et al. [40] and derive the analytical reparameterization of the trajectory reward  $r(\zeta)$  as:

$$r(\zeta, q) = \beta \log \frac{\pi_{\theta}(\zeta \mid q)}{\pi_{\text{ref}}(\zeta \mid q)} + \beta \log Z(\zeta).$$
 (3)

Similar to Rafailov et al. [40], we adopt the Bradley-Terry (BT) [5] model and model  $r_{\phi}$  from a set of trajectories ranked with preferences. Specifically, let  $\zeta_w$  and  $\zeta_l$  denotes the chosen and rejected trajectory starting from the same initial state, we can formulate the trajectory-wise reward modeling objective as:

$$P\left(\zeta_w \succ \zeta_l\right) = \frac{\exp\left(r(\zeta_w), q\right)}{\exp\left(r(\zeta_w), q\right) + \exp\left(r(\zeta_l), q\right)}.$$
 (4)

Then, we follow Rafailov et al. [40] and substitute Eq. (3) into Eq. (4) and obtain the following *trajectory-wise preference optimization (TPO)* loss  $\mathcal{L}_{TPO}$  equivalent to Eq. (2):

$$-\mathbb{E}_{(\zeta_w,\zeta_l)\sim\mathcal{D}}\left[\log\sigma\left(\beta\left(\log\frac{\pi_{\theta}(\zeta_w)}{\pi_{\text{ref}}(\zeta_w)}-\log\frac{\pi_{\theta}(\zeta_l)}{\pi_{\text{ref}}(\zeta_l)}\right)\right)\right],$$

where we can further draw from MDP and decompose the likelihood of a trajectory  $\zeta$  into individual state-action pairs, i.e.,  $\pi(\zeta,q) = \prod_{i=1}^T \pi(a_i \mid (o_i,q))$  and further obtain

$$\log \frac{\pi_{\theta}(\zeta, q)}{\pi_{\text{ref}}(\zeta, q)} = \sum_{t=1}^{T} \log \frac{\pi_{\theta}(a_i \mid (o_i, q))}{\pi_{\text{ref}}(a_i \mid (o_i, q))}.$$
 (6)

Then we can substitute Eq. (6) into Eq. (5) to obtain the TPO loss  $\mathcal{L}_{TPO}$  in terms of step-wise state-action pairs. Our

TPO loss Eq. (6) is beneficial as it: (1) aligns policy  $\pi_{\theta}$  globally towards human preferences on a trajectory level while simply using step-wise rollouts collected by VLAs; (2) it stabilizes the policy and steers it towards the final goal by backpropagating the gradients throughout all the state-action pairs along the trajectory; (3) it significantly boosts generalizability by learning from both successful and failed trajectories via a RL objective. Although Finn et al. [21] indicates that expanding the size of the sampled trajectory can reduce the bias in reward modeling, it also increases the training costs. Thus while our method can be easily scaled up, we keep our discussion to the binary case where only one chosen/rejected trajectory is present.

## 2.3. Guided-Cost Preference Generation

While given the TPO objective Eq. (5) we can align the policy towards arbitrary objectives defined through trajectories ranked by the corresponding preference, it incurs high costs as it requires human expertise and lengthy manual annotation. Thus to better scale up the preference synthesis towards arbitrary alignment objectives (e.g. task completion, safety, efficiency), we propose *Guided-Cost Preference Generation (GCPG)* to automatically curate such preferences that integrate different alignment objectives.

# 2.3.1 Multi-Stage Temporal Keypoint Constraints

Building on insights from Huang et al. [24], we address the complexity of specifying precise trajectory preferences for complex manipulation tasks by decomposing trajectories into temporal stages and assigning costs to quantify performance at each stage. Then, we aggregate these stagespecific costs to obtain a holistic evaluation for each trajectory. Specifically, we adopt a VLM-based stage decomposer  $\mathcal{M}_D$  (detailed in Appendix A), to partition a trajectory  $\zeta$  into a sequence of  $\mathbf{S}$  consecutive stages, formulated as

$$\{\zeta^1, \dots, \zeta^S\} = \mathcal{M}_D(\zeta, q), \quad \zeta^i = \{(o_t^i, a_t^i)\}_{t=1}^{T_i}, \quad (7)$$

where  $\zeta^i$  represents the  $i^{\text{th}}$  stage of trajectory  $\zeta$ .

After obtaining the stage decomposition, we further employ a vision-language model (e.g. DINOv2 [37]) to identify keypoints that serve as reference metrics across each stage. Then we prompt a powerful LLM [1] to propose multiple cost functions (see examples in Appendix E.2.) for each stage that correspond with the alignment objective, where lower cost indicates better objective compliance. Then the cost  $C^{S_i}$  at stage  $S_i$  is formulated as

$$C_{S_i} = \sum_{j=1}^{N_{S_i}} \beta_j \max(0, C_j^{S_i}(\{\kappa_{S_i}\} - \tau_j^{S_i}), \quad j \in \{1, \dots, N_{S_i}\},$$
(8)

where  $C_j^{S_i}(\{\kappa_{S_i}\})$  denotes the  $j^{\text{th}}$  cost calculated using a subset of keypoints  $\{\kappa_{S_i}\}$  in stage  $S_i$ .  $\tau_j^{S_i}$  is a tunable threshold parameter that adjusts the *tolerance* of each

cost [14], where the cost will only be applied when it exceeds the threshold.  $\beta_j$  is a weight parameter that adjusts the importance of each cost. Then to aggregate the costs for the entire trajectory, instead of summing each stage linearly, we apply an exponential decay to capture the casual dependencies of each temporal stage (e.g. if a trajectory incurs high costs in preceding stages it is not expected to perform well subsequently), defined as the *external reward*:

$$R_{\text{ext}}(\zeta) = \prod_{i=1}^{\mathbf{S}} e^{-\sum_{j=1}^{N_{S_i}} \beta_j \max(0, C_j^{S_i}(\{\kappa_{S_i}\} - \tau_j^{S_i}))}, \quad (9)$$

where Eq. (9) aggregates the individual costs and subobjectives from each stage to tackle the curse of dimensionality and effectively adhere to the customized alignment.

#### 2.3.2 Guided-Cost Preference Generation

To further improve the stability and optimality of the preference synthesis, we draw inspirations from self-rewarding [54] and determine that *a more optimal trajectory should be confirmed by both the external judge (as in Eq. (9)) and the model itself.* Thus we incorporate two additional rewards and obtain the GCPG reward:

$$R_{\text{GCPG}}(\zeta) = \lambda_1 R_{\text{self}}(\zeta) + \lambda_2 R_{\text{ext}}(\zeta) + \lambda_3 I_{\text{success}}(\zeta)$$
 (10)

where  $R_{\rm self}(\zeta)$  is the self-evaluated score provided by  $\pi$ , which equals the log-likelihood of generating trajectory  $\zeta$ :

$$R_{\text{self}}(\zeta) = \log(\pi(\zeta, q)) = \log(\prod_{i=1}^{T} \pi(a_i \mid (o_i, q)))$$
 (11)

and  $I_{\text{success}}(\zeta)$  is a binary indicator function that indicates whether the trajectory  $\zeta$  successfully completes the task:

$$I_{\text{success}}(\zeta) = \begin{cases} 1, & \text{if } \zeta \text{ is successful,} \\ 0, & \text{otherwise.} \end{cases}$$
 (12)

where  $\lambda$  are the weight parameters that adjust the importance of each reward. Intuitively, Eq. (11) can be seen as a dense approximation of the sparse signal provided by Eq. (12), which are further calibrated by Eq. (9) to obtain a holistic evaluation of the trajectory that accounts for both its optimality and degree of alignment to a customized objective specified through the external reward in Eq. (9).

## 2.4. Iterative Preference Optimization

After generating the preference, we then discuss our iterative preference optimization strategy. Inspired by the practices of on-policy RL [42] which often yield more optimal policy than off-policy training, we iteratively fine-tune the SFT VLA model via TPO with trajectories collected online.

For example, during the  $k^{th}$  iteration, we (1) first sample numerous trajectories for a variety of tasks and obtain  $\mathcal{D}^k$ ; (2) then we calculate the costs for each trajectory using Eq. (10) and rank these trajectories accordingly per task; (3) we pair the top-m and bottom-m trajectories with each other for each task, and obtain  $m^2$  chosen-rejected trajectory pairs; (4) then we fine-tune the same sampling policy with TPO via Eq. (5) and obtain an updated policy. We iterate this process for K times and obtain the final model aligned with the target objective. We detail the GRAPE iterative preference optimization procedure in Algorithm 1.

# Algorithm 1 GRAPE Iterative Preference Optimization

**Require:** Base VLA policy  $\pi_{\theta}$ , a collection of task instructions  $Q = \{q_i\}$ , stage decomposer  $\mathcal{M}_D$ , max iterations K, reward weights  $\{\lambda_1, \lambda_2, \lambda_3\}$ , stage-wise keypoints  $\{\kappa_{S_i}\}$  cost functions  $\{C_j^{S_i}\}$  and thresholds  $\{\tau_j^{S_i}\}$  **Ensure:** policy  $\pi^*$  aligned towards customized objective

## 3. Experiment

In this section, we evaluate GRAPE's performance in both real and simulated environments, addressing four key questions: (1) Does GRAPE improve the VLA model's performance relative to SFT-based baseline models? (2) How effective are guided-cost preference selection and iterative preference optimization in enhancing the model's performance? (3) What is the individual contribution of each reward component to overall model performance? (4) Can GRAPE support flexible alignment with different alignment objectives?

## 3.1. Experimental Setups

**Implementation Details.** We employ OpenVLA [26] as the backbone model, using LoRA fine-tuning with the AdamW optimizer for both supervised and preference fine-tuning. In the supervised fine-tuning stage, we use a learning rate of  $4 \times 10^{-5}$  with a batch size of 16. For preference fine-tuning,

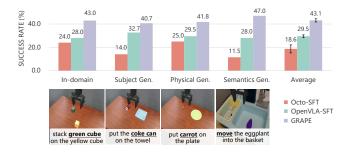

Figure 3. Comparison of GRAPE with OpenVLA and Octo finetuned on the same data on the Simpler-Env environment. We report the in-domain performance, which includes four tasks and three generalization evaluations (*subject*, *physical*, and *semantic*), where each incorporates multiple tasks.

we apply a learning rate of  $2\times 10^{-5}$  with the same batch size. Further details on the training process and datasets are available in Appendix A and B.

**Baseline Models.** We compare GRAPE with two leading robot learning models known for their strong performance in robot control tasks. The first model, Octo [44], is a large transformer-based policy model. The second, Open-VLA [26], is a 7B Vision-Language-Action model. Both models were supervised fine-tuned using the same dataset sampled from corresponding environments. We denote the supervised fine-tuned models as Octo-SFT and OpenVLA-SFT, respectively.

## 3.2. Evaluation in Simulation Environment

Evaluation Setup. We evaluate GRAPE's performance in two robot simulation environments: Simpler-Env [29] and LIBERO [33]. In Simpler-Env, we evaluate the model's in-domain performance as well as its generalization across three aspects: subject (generalize to unseen objects), physical (generalize to unseen object sizes/shapes), and semantic (generalize to unseen instructions) generalization. In LIBERO, we test our model on four tasks: LIBERO-Spatial, LIBERO-Object, LIBERO-Goal, and LIBERO-Long. All tasks are in-domain tasks. Additional details about the experimental setup are provided in Appendix C.2.

Results. We use the success rate across all tasks in Simple-Env and LIBERO as our primary evaluation metric, while we also record the grasping rate in Simpler-Env. The results of Simple-Env and LIBERO are reported in Figure 3 and Figure 4, respectively. According to the results, we can observe that GRAPE outperforms Octo-SFT and OpenVLA-SFT in Simpler-Env by an average of 24.48% and 13.57%, respectively. GRAPE outperforms Octo-SFT and OpenVLA-SFT in LIBERO by an average of 4.1% and 2.7%, respectively. Additional results can be found in Appendix D. While GRAPE significantly boosts in-domain performance, it equivalently enhances the generalizability of VLA policies on OOD tasks, given the task completion

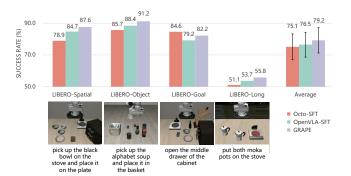

Figure 4. Comparison of GRAPE with OpenVLA and Octo finetuned on the same data on the LIBERO environment. We report the performance on four LIBERO tasks, including LIBERO-Spatial, LIBERO-Object, LIBERO-Goal, LIBERO-Long.

alignment on a trajectory level.

#### 3.3. Evaluation in Real-World Robot Environment

Evaluation Setup. We conducted 280 real-world experiments across 28 tasks to evaluate the generalization capabilities of GRAPE. The evaluation focus on in-distribution evaluation and five out-of-distribution generalization types: visual, subject, action, semantic, and language grounding generalizations. Here, visual generalization assesses the ability to adapt to new visual environments; subject generalization evaluates the recognition and handling of unfamiliar objects; action generalization measures performance across diverse actions; semantic generalization evaluates responses to prompts with similar meanings; and language grounding generalization gauges comprehension of spatial directions. Detailed experimental setup are provided in Appendix C.1 and illustrated in Figure 5.

Results. In the real-world experiment, GRAPE significantly outperforms other models across a variety of tasks. Notably, in in-domain tasks, GRAPE achieves a success rate of 67.5%, which is a 22.5% improvement over OpenVLA-SFT's 45% and substantially higher than Octo-SFT's 20%. Additionally, in visual generalization tasks, GRAPE demonstrates higher adaptability with a success rate of 56%. In the more challenging action generalization tasks, although OpenVLA-SFT shows modest performance, GRAPE still outperforms OpenVLA-SFT, indicating its potential in understanding various actions and executing commands based on language. Considering tasks across all categories, GRAPE's total average success rate is 52.3%, marking a 19% improvement over OpenVLA-SFT's 33.3% and significantly ahead of Octo-SFT's 5.8%. This performance highlights GRAPE's effectiveness and high adaptability in handling complex and variable task environments.

#### 3.4. Ablation Study of Reward Model

In this section, we conduct an ablation study to analyze the contribution of each reward component in Eq. (10) to

Figure 5. Comparison of GRAPE with OpenVLA and Octo fine-tuned on the same data on the real-world environment. We report the in-domain performance, which includes four tasks and five generalization evaluations (*visual*, *subject*, *action*, *semantic*, and *language* grounding), where each incorporates multiple tasks. We also report the average performance across all tasks.

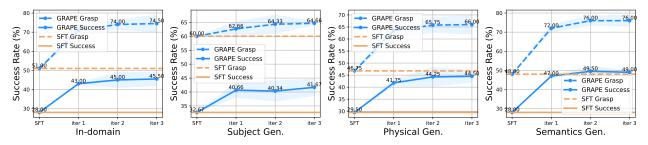

Figure 6. Performance of GRAPE during iterative preference optimization via TPO. We demonstrate the average success rate for each iteration across in-domain tasks and three types of generation tasks (*subject*, *physical*, *semantics*).

the final performance: the external objective-aligned reward  $R_{\rm ext}(\zeta)$ , the self-evaluated reward  $R_{\rm self}(\zeta)$ , and the success indicator  $I_{\rm success}(\zeta)$ . Additionally, we perform a separate ablation study to emphasize the importance of utilizing the entire reward score for preference selection. This approach is compared against a method that randomly selects one successful trajectory as the preferred trajectory and one failed trajectory as the rejected trajectory. The results in the Simpler-Env environment are reported in Table 1.

The results indicate that: (1) incorporating the full reward score Eq. (10) for preference ranking significantly enhances performance compared to random selection based on success alone; (2) all reward components contribute to improving model performance. These findings align with our expectations. Specifically,  $R_{\rm self}(\zeta)$  enhances the robustness of the GRAPE model by encouraging it to select trajectories with higher generation probabilities. In parallel,  $R_{\rm ext}(\zeta)$  guides the model toward learning specific behaviors, such as safety and efficiency. Finally,  $I_{\rm success}(\zeta)$  serves

as a critical indicator, steering the model to prioritize successful trajectories.

## 3.5. Analysis of Iterative Preference Optimization

In this section, we analyze the iterative preference optimization performance. We conduct the experiments on the Simpler-Env environment and report the results with respect to the training iterations in Figure 6. Here, SFT means the supervised fine-tuned OpenVLA model before preference optimization. In our experiments, GRAPE achieves 17.5%, 9.0%, 15.0%, 21.0% improvements in in-domain performance, subject generalization, physical generalization and semantic generation, respectively. The findings suggest that GRAPE progressively enhances model performance across iterations, showcasing its ability to enhance the quality of generated preference data and achieve better generalization. Notably, the magnitude of improvement diminishes over time, aligning with our expectations as the model approaches convergence.

Table 1. Ablation study of reward score. Here, Random w/  $I_{\text{success}}$  refers to randomly selecting one successful trajectory as the chosen trajectory and one failed trajectory as the rejected trajectory,  $R_{\text{self}}(\zeta)$  is the self-evaluated score provided by the log-likelihood of generating trajectory  $\zeta$ ,  $R_{\text{ext}}(\zeta)$  represents objective-aligned multi-stage reward defined in Eq. (9),  $I_{\text{success}}(\zeta)$  is a binary indicator function that indicates whether the trajectory  $\zeta$  successfully completes the task.

	In-domain		Subject Gen.		Physical Gen.		Semantics Gen.		Average

# 3.6. Analysis of Different Alignment Objectives

After demonstrating the effectiveness of GRAPE in improving the generalization of the VLA model (measured by success rate), we further investigate its potential to align the model with flexible objectives, such as efficiency and safety. Revisiting Eq. (9), we observe that adjusting the threshold parameters can guide the model to prioritize specific objectives by influencing trajectory preference selection. In this study, we focus on two new alignment objectives: safety and efficiency. Safety aims to minimize collisions between the robot and objects, while efficiency seeks to reduce the average number of steps required for the robot to complete a task. To achieve these objectives, we set a lower threshold for collision costs to emphasize safety and a lower threshold for path costs to prioritize efficiency. These modified settings are then applied to the original real-world and simulation evaluations. We train models to align with the safety and efficiency objectives, referring to these models as GRAPE-Safety and GRAPE-Efficiency, respectively (see detailed experimental setup in Appendix C.2).

The results are reported in Table 2, where we use collision rates, step lengths, and success rates to evaluate safety, efficiency and generalization capabilities, respectively. According to Table 2, the GRAPE-Safety and GRAPE-Efficient have better performance on collision rate

and step length respectively, meanwhile maintain a comparable success rate, compared with OpenVLA-SFT. The results indicate that GRAPE can be easily adapted to account for flexible alignment objectives such as safety, efficiency by adjusting the multi-stage cost functions accordingly, while incurring minimal drop in task success rate.

# 3.7. Case Study

We further demonstrate a case study in Figure 7 to analyze GRAPE's adaptability towards different alignment objectives. Specifically, we consider a safety-critical pickup task where an obstacle is placed between the object and the target. Specifically, OpenVLA-SFT fails to complete the task without preference alignment. However, we can see that while GRAPE aligned towards task completion (on the second-row of Figure 7) can effectively pick up and place the object, it also collides with the obstacle, due to the policy is aligned to aggressively boost task success without explicitly addressing safety concerns. On the contrary, GRAPE-safety learns to avoid colliding with the obstacle while efficiently completing the task. Both Table 2 and Figure 7 indicates that by simply tweaking the cost function, GRAPE can effectively adapt to different objectives. More cases could be found in Appendix E.1.

#### 4. Related Works

#### 4.1. Vision-language-action Models

Previous robot learning works [14, 23, 24, 30, 31, 34, 35] typically take a hierarchical planning strategy. For example, Code as Policies [31] and EmbodiedGPT [35] adopt LLMs and VLMs to generate a sequence of high-level action plans first and further leverage a low-level controller to solve for local trajectories. However, such models suffer from limited low-level skills and are hard to generalize to everyday tasks. VLAs tend to scale up low-level tasks by incorporating large vision-language models as backbones and directly generating actions within the model. They generally achieve action planning via two mainstream approaches:

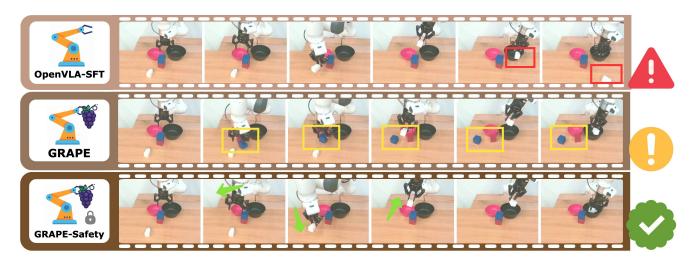

Figure 7. Comparison of GRAPE aligned via *safety* objective with GRAPE aligned via *task-completion* objective and OpenVLA-SFT. Specifically, we assess their performance on a safety-critical task with the instruction: *pick up the white box and place into the black pot*.

(1) Discretization of action space [6, 7, 26], such as Open-VLA [26], which preserves the autoregressive language decoding objective and uniformly truncate the action space into a small set of *action tokens*. As such discretization unavoidably introduces errors, some methods such as [4] adopt more recent structures [53] and directly integrate diffusion heads for action prediction which avoids discretization. (2) Diffusion models [2, 16, 18, 25, 32, 49] like Diffusion Policy [16] as the action head, which instead of generating one stepwise action each time, produces a sequence of future actions through several denoising steps.

While these models vary in structure, they are consistently supervised-trained on successful rollouts via behavior cloning, which can hardly be generalized to unseen manipulation tasks. However, our GRAPE first aligns VLA policies on a trajectory level via trial and error, effectively boosting generalizability and customizability.

# 4.2. Reinforcement Learning and Preference Optimization

Reinforcement learning (RL) [17, 42, 56] plays a pivotal role in the post-training of SOTA foundation models (FMs), including text generation models [1, 12, 15, 19, 39], image generation models [13, 20], video generation [50], which has been extensively leveraged to align the pre-trained FMs to comply with human values embedded through preference data. In the meantime, RL has also shown tremendous success in training policies for robotics tasks [10, 11, 14, 42, 47, 48, 55]. While it is intuitively beneficial to post-align VLA via RL, no prior works have reported such success, mainly due to that (1) manipulation objectives are usually diverse and complex, which makes the reward hard to define analytically [21]; (2) and while such reward can be modeled from human preferences, annotating such preferences in robotics manipulation tasks are usually lengthy and

requires human expertise [45]; (3) the imperfect numerical differentiation of rewards usually leads RL algorithms such as PPO [42] to collapse [8]. However, a recent line of works [40, 46] has shown success in directly aligning the policy via RL without such explicit reward modeling. Inspired, GRAPE aligns the policy by contrasting trajectories with each other, avoiding the numerical issues in rewarding modeling. Besides, we introduce an automatic preference synthesis pipeline that easily scales with diverse manipulation tasks and can adapt to different alignment objectives.

# 5. Conclusion and Discussion

In this work, we addressed the critical challenges faced by vision-language-action (VLA) models, including limited generalizability and adaptability to diverse manipulation objectives. We proposed GRAPE, which aligns VLA policies on a trajectory level. GRAPE enhances generalizability by learning from both successful and failed trials, offering flexibility in aligning with objectives such as safety, efficiency, and task success through customized spatiotemporal constraints. Experimental results demonstrated significant improvements, with GRAPE enhancing success rates on both in-domain and unseen tasks while enabling flexible alignment. While GRAPE demonstrates significant improvements in generalization and alignment flexibility, it has several limitations. First, the reliance on preference ranking requires a sufficient diversity of trajectories, potentially restricting the application in scenarios where only limited task settings are available. Second, while GRAPE supports customizable alignment, the manual tuning of threshold parameters for specific objectives may introduce subjective biases and require domain expertise. Future work may explore more efficient and automated methods for preference synthesis and adaptation.

# **Author Contribution**

We detail the author's contribution in this section. Conceptualization: Huaxiu Yao; Methodology: Zhaorun Chen, Chaoqi Wang, Mingyu Ding, Huaxiu Yao; Preference Optimization Model Implementation: Zijian Zhang; Simulation Experiment: Zijian Zhang; Real-world Experiment: Kaiyuan Zheng, Joel Jang, Yi Li; Paper Writing and Discussion: All Authors.

# A. Additional Description of GRAPE and Hyperparameter Settings

Customized Cost Generation. In our real-world experiments, we first input image-text pairs containing prompts and initial states into the Vision-Language Model (VLM) Hamster [30]. Using the stage information and stage points generated by Hamster, we segmented the collected trajectories. This helps analyze complex task sequences more precisely, giving detailed attention to each stage. And we utilized Grounded-SAM [41] or methods combining SAM [41] and DinoV2 [38] to extract key point information from the images. These key points, combined with our self-collected trajectory data, enable us to refine the execution steps and path planning of tasks based on the stage information generated by the Hamster model. For example, for a simple pick-and-place task, we can decompose it into multiple explicit stages: Grasp the grape, Move the grape onto the plate, Place the grape on the plate.

To generate detailed operational information and cost functions for each stage, we utilized GPT-40 [1] with customized prompts. This approach makes stage planning more precise and efficient, allowing us to meet specific task requirements and constraints. Furthermore, we enhanced our method by incorporating various task-specific constraints, including: **Collision constraints:** Ensuring the robot avoids collisions with obstacles. **Path constraints:** Optimizing the efficiency and safety of the robot's movement path. By adopting this strategy, we achieve greater flexibility and specificity in task planning, and better adapting to different task scenarios.

Iterative Preference Optimization. For Iterative Preference Optimization, we first utilize the fine-tuned VLA model for online data sampling. For each task, we sample  $\mathcal{N}_t$  trajectories to facilitate further selection. To simplify the experimental setup, we set  $\mathcal{N}_t = 5$  for each task, which has been found to perform effectively in practice.

After sampling, each trajectory is automatically labeled using the GCPG reward, as defined in Eq. (10). Based on the distribution of  $R_{\rm self}$ ,  $R_{\rm ext}$ , and  $I_{\rm success}$  observed in preliminary experiments, we set  $\lambda_1=0.01$ ,  $\lambda_2=0.01$ , and  $\lambda_3=2$ . These values ensure that  $R_{\rm self}$ ,  $R_{\rm ext}$ , and  $I_{\rm success}$  contribute comparably to the final reward value. Subsequent experiments validate the reasonableness of these parameter choices. Using the GCPG reward assigned to each trajectory, we identify the trajectory with the highest reward as  $y_w$  and the trajectory with the lowest reward as  $y_l$  for each task. This selection process enables the construction of the TPO Dataset,  $\mathcal{D}_{traj}$ , for TPO training.

For the TPO training process, we employ LoRA [22] and the AdamW optimizer, setting the learning rate to  $2 \times 10^{-5}$  and the batch size to 16. The model is trained for a single epoch before being utilized for iterative online sampling. During iterative online sampling, the experimental settings remain consistent with the aforementioned descriptions.

# **B.** Detail Experiment Datasets

In this section, we describe the datasets collected for supervised fine-tuning (referred to as the SFT dataset) and preference alignment (referred to as the TPO dataset).

# **B.1. Real-World Dataset**

**SFT Dataset.** In our real-world robot experiments, we use a robotic platform composed of a Franka robotic arm and a Robotiq gripper for data collection. To ensure consistency in data collection and evaluation, all operations are performed in the same experimental environment.

During data collection, we gathered a dataset of 220 instances of pick and place tasks involving common objects such as bananas, corn, milk, and salt. Additionally, we collected data on 50 instances of tasks involving pressing buttons of different colors. Since the number of objects used for the button-pressing tasks is limited, we introduced background noise and interfering objects during the testing phase to create unseen scenarios.

To further enhance the capabilities of OpenVLA in handling different actions, we also collected data on 50 instances of knock down tasks. These diverse task datasets help improve the model's generalization ability in processing different types of actions.

**TPO Dataset.** In the real-world experiments, we utilized a model fine-tuned on the real-world SFT dataset via OpenVLA for trajectory sampling. Each task was conducted five times. In the TPO dataset, we experimented with 15 different tasks, including 10 pick and place tasks, 3 push button tasks, and 2 knock down tasks, accumulating a total of 75 data entries. After a selection process, we derived a preference dataset consisting of 30 trajectories.

# **B.2. Simulation Datasets**

**SFT Dataset:** For Simpler-Env, the SFT dataset comprises 100 trajectories, amounting to approximately 2,900 transitions. These rollouts are generated from Simpler-Env using Octo, following the methodology described in Ye et al. [51]. For

LIBERO, it is worth noting that we neither collect new data nor fine-tune the OpenVLA model. Instead, we directly utilize the OpenVLA-SFT model provided by the OpenVLA team, which significantly streamlines the pipeline.

**TPO Dataset.** In the case of Simpler-Env, trajectories are sampled for each task using the OpenVLA-SFT model, with five trials conducted per task. This process yields a TPO dataset consisting of 80 trajectories. For LIBERO, OpenVLA-SFT models (one model per task) are employed to sample data across four tasks in LIBERO. For each task, five trajectories are sampled for each sub-task, resulting in a TPO dataset comprising a total of 20 trajectories.

# C. Detailed Experiment Settings and Additional Result

#### C.1. Real-World

# C.1.1 Real-World Experiment Setup

In real-world experiment, we used the Franka robot arm, which is known for its precision and flexibility. However, we encountered a problem with the original Franka gripper, which was not long enough, limiting our ability to handle some of the tasks, resulting in inefficient completion and a high failure rate. To solve this problem, we decided to replace the original Franka grippers with Robotiq grippers, which are not only longer, but also provide more grip and flexibility, which greatly improves the efficiency and success rate of the tasks.

The purpose of this experiment was to assess the cross-task generalization capabilities of OpenVLA under the GRAPE framework and to compare its performance with several baseline models. Considering the generally poor zero-shot generalization performance of most VLA models, we performed supervised fine-tuning using the comprehensive rollout dataset  $D_T$  collected from real scenes to construct a fine-tuned model. The selection of baseline models included those adjusted with domain-specific data, as well as the Octo model, RVT-2 model, and OpenVLA-SFT model.

## C.1.2 Real-World Tasks

As shown in Figure 5, we performed a comprehensive evaluation on a real machine for several tasks. These tasks cover five different generalization scenarios: Visual Generalization, Subject Generalization, Action Generalization, Semantics Generalization, and Language Grounding. Specifically, for each generalization scenario, we set the following tasks:

- Visual Generalization includes 8 tasks, e.g., pick up the GRAPE and put it in the black bowl, with noise objects and noisy backgrounds. Some tasks have only noisy backgrounds.
- Subject Generalization includes 4 tasks, e.g., pick up the K and put it in the black bowl.
- Action Generalization includes 5 tasks, e.g., knock down the green bottle.
- Semantics Generalization includes 4 tasks, e.g., stack carrot and put it on the blue plates.
- Language Grounding includes 3 tasks, e.g., pick up left object to left plate.

We conducted experiments on 28 total different tasks, attempting each task ten times, totaling 280 executions. To ensure fairness in the evaluation, we maintained the same starting position in each model test. Additionally, we matched the image resolution when training all models and used exactly the same initial object positions in all evaluations. We set specific success criteria for each task. For example, in the pick-and-place task, a successful grasp is defined as successfully grasping the target object. In the push-button and knock-down tasks, a successful grasp is defined as correctly approaching and manipulating the target object. Overall task success is defined as the object being accurately placed at the target location, successfully knocked down, or the target button being successfully pressed. Due to the strictness of these criteria, some models found it difficult to achieve success in specific tasks.

Table 3. Comparison of GRAPE models in different iteration rounds. We assess their performance in in-domain tasks and three kinds of generalization evaluations. Each task's performance is evaluated on the overall grasp rate and success rate.

	In-domain		Subject Gen.		Physical Gen.		Semantics Gen.		Average	
	Grasp	Success	Grasp	Success	Grasp	Success	Grasp	Success	Grasp	Success
Iter-1	71%	43%	62.67%	40.67%	63.5%	41.75%	72%	47%	67.29%	43.11%
Iter-2	74%	45%	64.33%	40.33%	65.75%	44.25%	76%	49.5%	70.02%	44.77%

# **C.2. Simulation Experiments**

# C.2.1 Simpler-Env

We utilize Simpler-Env [29] as the experimental environment in our study. SIMPLER [29] (Simulated Manipulation Policy Evaluation for Real Robot Setups) is a collection of simulated environments created to assess robot manipulation policies in a way that closely reflects real-world scenarios. By leveraging simulated environments, SIMPLER effectively serves as a practical alternative to real-world testing, which is often costly, time-consuming, and challenging to replicate.

**Simpler-Env Tasks.** In our paper, we use four in-domain tasks from WidowX robot in Simpler-Env. We also design three kinds of generalization tasks in Simpler-Env. These tasks are described below:

## **In-Domain Tasks Shown in Fig. 3:**

- 1. Put Carrot on Plate: The robot is positioned in front of a platform with a plate and a carrot. The robot's goal is to grasp the carrot and put it onto the plate.
- 2. Put Eggplant in basket: The robot is positioned in front of a sink with a basket and a Eggplant. The robot's goal is to grasp the Eggplant and put it in the basket.
- 3. Stack Green Cube on Yellow Cube: The robot is positioned in front of a platform with a green cube and a yellow cube. The robot's goal is to grasp the green cube and stack it on the yellow cube.
- 4. Put Spoon on towel: The robot is positioned in front of a platform with a spoon and a towel. The robot's goal is to grasp the spoon and put it on the towel.

# Three Kinds of Generalization Tasks Shown in Fig. 3:

- 1. Subject Generalization: The robot is positioned in front of a platform, similar to the environment in in-domain tasks. But the robot's goal is to grasp some new objects(i.e. pepsi can, coke can, sprite can) and put it onto the plate.
- 2. Physical Generalization: The robot is positioned in front of a platform, similar to the environment in in-domain tasks. But the robot's goal is to grasp some original objects with different sizes and collision boxes, then put it onto the plate.
- 3. Semantics Generalization: The robot is positioned in front of a platform, similar to the environment in in-domain tasks. And the instruction is similar to in-domain tasks, too. But the instruction has been modified by GPT-40 [1] while maintaining its original meaning.

## C.2.2 LIBERO

We further utilize LIBERO [33] as the experimental environment in our study. LIBERO (LIfelong learning BEnchmark on RObot manipulation tasks) includes a set of 130 language-conditioned robot manipulation tasks inspired by human activities, organized into four distinct suites. Each suite is crafted to examine distribution shifts in object types, spatial arrangements of objects, task goals, or a combination of these factors. LIBERO is built to be scalable, extendable, and specifically tailored for advancing research in lifelong learning for robotic manipulation.

**LIBERO tasks** In our paper, we use four in-domain tasks from LIBERO, which are shown in Fig. 4. These tasks is described below:

- 1. **LIBERO-Spatial** includes the same set of objects arranged in various layouts, testing the model's ability to understand spatial relationships.
- 2. **LIBERO-Object** features consistent scene layouts with varying objects, evaluating the model's ability to understand different object types.
- 3. **LIBERO-Goal** includes of the same objects and layouts but different task goals, testing the model's knowledge of different task-oriented behaviors.
- 4. LIBERO-10 consists of long-horizon tasks with diverse objects, layouts, and tasks.

Eash task mentioned above has 10 sub-tasks, with similar task instructions and scenes.

# D. Additional Real-World and Simulation Results

We provide additional results in Table 4, Table 5, and Figure 13 with detailed task description. Each table has in-domain tasks and several kinds of generalization evaluations. These experiments are conducted across Octo-SFT, OpenVLA-SFT and GRAPE.

Table 4. We present the performance of various action policy on real-world robotic manipulation tasks categorized by different types of generalization. The tasks include in-domain, visual generalization with and without noise, subject generalization, action generalization, semantics generalization, and language grounding. Each task's performance is evaluated based on the number of successful grasps and the overall success rate, comparing results from Octo-SFT, OpenVLA-SFT, and GRAPE. Average success rates are calculated for each generalization category to demonstrate the effectiveness of the tested models under different conditions.

Generalization	Task		o-SFT	OpenVLA-SFT		GRAPE	
		Grasp	Success	Grasp	Success	Grasp	Success
	pick up the corn and put it in the black bowl	3	3	2	2	8	7
	pick up the banana and put it in the black bowl	2	0	6	6	9	7
In-domain	pick up the milk and put it in the white bowl	4	2	10	8	9	9
	pick up the salt bottle and put it in the white bowl	4	3	4	2	6	4
	Average	32.5%	20%	55%	45%	80%	67.5%
	pick up the corn and put it in the black bowl	2	1	6	3	6	6
	pick up the banana and put it in the black bowl	0	0	3	2	4	1
Visual Generalization	pick up the milk and put it in the white bowl	4	0	4	4	9	7
(w/o noise background)	pick up the salt bottle and put it in the white bowl	2	2	6	5	8	8
	pick up the GRAPE and put it in the black bowl	0	0	6	5	8	6
	Average	16%	6%	50%	38%	70%	56%
	pick up the GRAPE and put it in the black bowl	1	0	4	2	6	4
Visual Generalization	pick up the milk and put it in the white bowl	2	1	7	5	5	4
(w/o noise background and object)	pick up the salt bottle and put it in the white bowl	0	0	2	2	8	8
	Average	10%	3.3%	43.3%	30%	63.3%	53.3%
	pick up the chips and put it in the red bowl	4	0	2	2	6	5
	pick up the K and put it in the black bowl	2	0	4	4	7	6
Subject Generalization)	pick up the box juice and put it in the yellow plate	2	0	8	3	8	6
	pick up the Fanta can and put it in the white bowl	2	2	4	1	6	4
	Average	25%	5%	45%	25%	67.5%	52.5%
	push down the blue button	1	0	4	4	6	6
	push down the green button	1	0	6	4	4	4
Action Generalization	push yellow the button	2	2	6	3	8	5
Action Generalization	knock down the green bottle	3	1	2	2	4	2
	knock down the popcorn	0	0	4	2	4	3
	Average	14%	6%	44%	30%	52%	40%
	take green pepper and place it in the black bowl	0	0	10	6	10	8
	move icecream and put it in the red bowl	0	0	6	4	4	4
Semantics Generalization	stack carrot and put it on the blue plates	0	0	8	8	6	6
	Lift GRAPE and place it in the black bowl	0	0	2	0	2	2
	Average	0%	0%	65%	45%	55%	50%
	pick up left object to left plate	0	0	4	0	5	2
Language Grounding	push down right button	0	0	6	2	8	7
Language Grounding	pick up right object to right plate	0	0	4	4	6	5
	Average	0%	0%	46.7%	20%	63.3%	46.7%
Total Average		13.9%	5.8%	49.8%	33.3%	64.3%	52.3%

# E. Case Study

# E.1. Case Study of Real-World Generation Tasks

We provide an illustration for each specific task included in the suite evaluation for *in-domain* tasks in Figure 8 and for each type of generation task, including *subject generalization* in Figure 9, *language grounding* in Figure 10, *visual generalization* in Figure 11, *action generalization* in Figure 12, and *semantic generalization* in Figure 13. Specifically, we demonstrate the initial and final states of GRAPE in handling each of these challenging tasks, as detailed in the corresponding captions.

Table 5. We comparesthe performance of Octo-SFT, OpenVLA-SFT, and GRAPE across various robotic tasks within in-domain, subject, physical, and semantics generalization categories. It shows grasp percentages and success rates for each task, illustrating how each VLA performs under different generalizations.

Generalization	Task	Octo-SFT		OpenVLA-SFT		GRAPE	
		Grasp	Success	Grasp	Success	Grasp	Success
In-domain	put the carrot on the plate	32%	16%	36%	30%	68%	48%
	put the eggplant in the basket	70%	44%	58%	32%	84%	48%
	stack the green cube on the yellow cube	52%	0%	56%	20%	76%	40%
	put the spoon on the towel	54%	36%	52%	28%	56%	34%
	Average	52%	24%	51%	28%	71%	43%
	put the coke can on the towel	24%	14%	60%	38%	78%	32%
Subject Generalization	put the pepsi can on the towel	28%	16%	58%	38%	64%	50%
(unseen objects)	put the sprite can on the towel	24%	12%	62%	22%	46%	40%
	Average	25.33%	14%	60%	32.67%	62.67%	40.67%
	put the carrot on the plate(size:0.5)	38%	22%	56%	38%	78%	64%
	put the carrot on the plate(size:1.1)	26%	12%	32%	24%	64%	42%
	put the carrot on the plate(wider collision box)	28%	16%	34%	26%	62%	42%
District Consult of the	put the carrot on the plate(longer collision box)	32%	14%	38%	30%	66%	48%
Physical Generalization (unseen object sizes/shapes)	put the spoon on the towel(size:0.5)	62%	38%	66%	40%	72%	38%
(unseen object sizes/snapes)	put the spoon on the towel(size:1.1)	52%	32%	50%	28%	56%	30%
	put the spoon on the towel(wider collision box)	48%	30%	44%	24%	50%	32%
	put the spoon on the towel(longer collision box)	56%	36%	54%	26%	60%	38%
	Average	42.75%	25%	46.75%	29.5%	63.5%	41.75%
	put the vegetable on the plate	16%	6%	32%	28%	66%	48%
Semantics Generalization	move the eggplant into the basket	18%	8%	50%	30%	78%	44%
(unseen instructions)	put the green cube onto the yellow cube	32%	6%	62%	26%	88%	60%
	place the spoon onto the towel	42%	26%	48%	28%	56%	36%
	Average	27%	11.5%	48%	28%	72%	47%
Total average		36.77%	18.63%	51.44%	29.54%	67.29%	43.11%

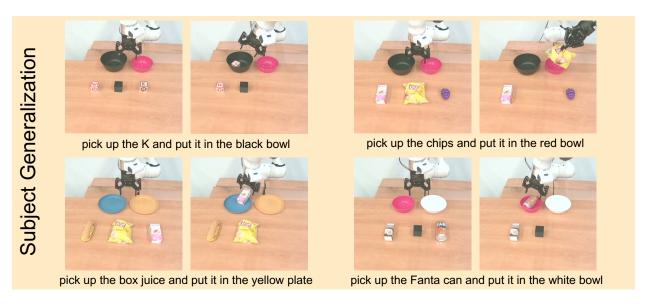

Figure 9. Illustrations of real-world tasks that we evaluated for *subject generation*, where we report the detailed results in Table 4. Specifically, we demonstrate the initial and final state of GRAPE in handling each of the four challenging tasks detailed in the captions.

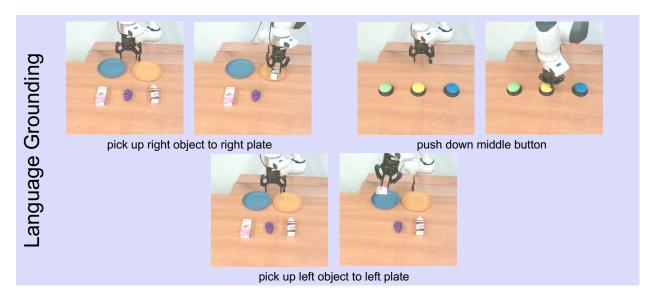

Figure 10. Illustrations of real-world tasks that we evaluated for *language generation*, where we report the detailed results in Table 4. Specifically, we demonstrate the initial and final state of GRAPE in handling each of the five challenging tasks detailed in the captions.

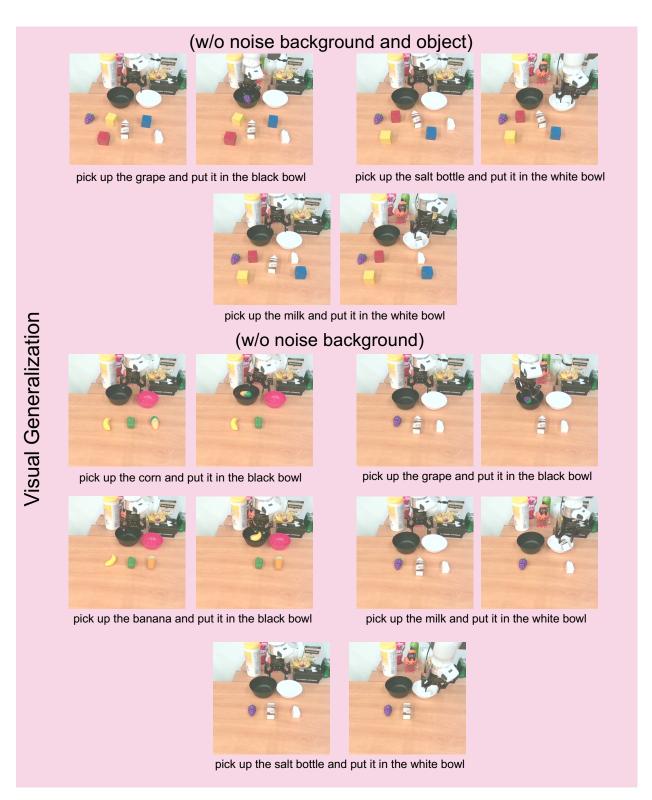

Figure 11. Illustrations of real-world tasks that we evaluated for *visual generation*, where we report the detailed results in Table 4. Specifically, we demonstrate the initial and final state of GRAPE in handling each of the eight challenging tasks detailed in the captions.

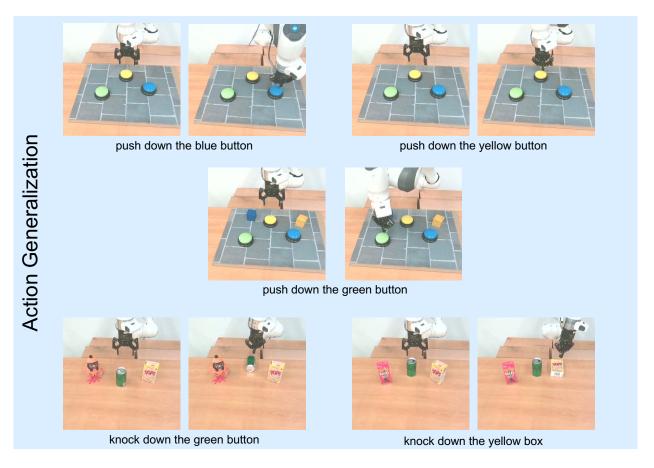

Figure 12. Illustrations of real-world tasks that we evaluated for *action generation*, where we report the detailed results in Table 4. Specifically, we demonstrate the initial and final state of GRAPE in handling each of the five challenging tasks detailed in the captions.

Figure 13. Illustrations of real-world tasks that we evaluated for *semantic generation*, where we report the detailed results in Table 4. Specifically, we demonstrate the initial and final state of GRAPE in handling each of the four challenging tasks detailed in the captions.

# E.2. Case Study of Multi-stage Cost Functions

We demonstrate some case studies of the multi-stage cost functions generated using our proposed pipeline given different alignment objectives.

# **E.2.1** Task Completion

```
Cost Functions for Task Completion Alignment
    # The task involves picking up the grape and placing it in the black bowl.
    # The stages involved are:
    # 1. Grasp grape
    # 2. Move grape to black bowl
    # 3. Drop grape in black bowl
    num stages = 3
    ### stage 1: Grasp grape
    def stage1 target constraint1(end effector, keypoints):
        """Align the end-effector with the grape's center."""
        grape_center = keypoints[0]
        target_cost = np.linalg.norm(end_effector - grape_center)
        return target_cost
    ### stage 2: Move grape to black bowl
    def stage2_target_constraint1(end_effector, keypoints):
        """Calculate the relative distance between grape and black bowl."""
        black_bowl_center = keypoints[1] # Assuming keypoint 1 is the black bowl
        target_cost = np.linalg.norm(end_effector - black_bowl_center)
        return target_cost
    ### stage 3: Drop grape in black bowl
    def stage3_target_constraint1(end_effector, keypoints):
        """Ensure the grape rests in the black bowl."""

```

# Prompt Template for Multi-stage Cost Proposal

#### **USER: Instructions**

The image shows a robot stage point in a workspace, each point in the diagram represents the point of the stage split:

- Stage\_point\_0 : Represents the initial position of the carrot.
- Stage\_point\_1: Represents the intermediate position above the carrot for grasping.

Determine how many stages are involved in the task. Grasping must be an independent stage. Some examples:

#### 1. Task: Put the carrot on the plate

#### **Stages:**

- · Grasp carrot
- Move carrot to plate
- Drop carrot on plate

# Stage 1: Grasp carrot

- Path constraints:
  - Align the end-effector with the carrot's center.
- Collision constraints:
  - The end-effector must approach the carrot from above to avoid collision.

## Stage 2: Move carrot to plate

- Path constraints:
  - Calculate the relative distance between carrot and plate.
- Collision constraints:
  - The carrot is aligned above the plate.

# Stage 3: Drop carrot on plate

- Path constraints:
  - The carrot must rest on the plate.
  - The carrot should not bounce out of the basket.
- Collision constraints:
  - The end-effector must approach the carrot from above to avoid collision.

# Note:

- Sum all Path constraints cost the path cost variable.
- Sum all Grasp constraints cost the grasp\_cost variable.
- Sum all Collision constraints cost the collision\_cost variable.
- Each constraint function takes an end-effector point and a set of keypoints as input, returning a numerical cost. The constraint is satisfied if this cost is zero or less.
- Define any number of path constraints per stage, but avoid using "if" statements in the functions.
- Avoid using path constraints when manipulating deformable objects (e.g., towels).
- Input format:
  - end\_effector: np.array of shape (3,) representing the end-effector position.
  - keypoints: np.array of shape (K, 3) representing the keypoints positions.
- Use Python and NumPy functions freely in constraint functions.
- Use pairs of keypoints to create vectors if needed.
- Keypoints are indexed starting from 0, matching their order in the keypoints array.

## Structure your output in a single Python code block as follows:

```
# ...
    num_stages = ?
    ### stage 1 path constraints (if any)
    def stage1_path_constraint1(end_effector, keypoints):
        """Put your explanation here."""
        return path_cost
    # Add more constraints if needed
    ### stage 1 collision constraints (if any)
    def stage1_collision_constraint1(end_effector, keypoints):
        """Put your explanation here."""
        return collision_cost
    # Add more constraints if needed
    # Repeat for more stages
